Summary:

Ore-element ratio analysis of 67 sulphide occurrences from two meta-sedimentary units in the Scandinavian Caledonides, has shown that the proportional distribution of Zn and Pb are similar in the two groups, whereas the distribution of Cu, Ag and Au vary between them. One of the units, known as the Mofjellet Group, is relatively enriched in Au and Ag whereas the Plurdalen Group is enriched in Cu. In both groups, The average zinc ratio ($100\text{Zn}/(\text{Zn}+\text{Pb})$) in both groups is 86. Assuming that the ore-bearing solutions were saturated with Zn and Pb, this ratio may suggest relatively low temperatures of the ore-forming solutions, a salinity in excess of ca. 2 M NaCl and/or partial complexing of Zn by bisulphide ions. Proportionally higher concentrations of Cu in the Plurdalen Group are due to increased stability of bisulphide complexes which, selectively, would enhance and/or maintain the Cu solubility in the ore-bearing solutions and lower the concentration of Zn and Pb. This study also imply that a Zn-Pb deposit discovered in the Mofjellet Group might benefit from recoverable concentrations of Ag and Au, whereas a deposit in the Plurdalen Group, besides Zn and Pb, potentially could benefit from economic concentrations of Cu.

5 INTRODUCTION

Analysis of the proportions between Zn, Pb, Cu, Ag and Au can provide us with important information about the ore-forming conditions and the sedimentary environment in which sulphide occurrences formed. The ratios that are considered might vary from one area to the other, but in the present study we found that the ratios $100\text{Zn}/(\text{Zn}+\text{Pb})$ (also known as the zinc ratio), Cu/Zn , Cu/Pb , Cu/Ag , S/Fe $\text{Au}/(\text{Zn}+\text{Pb}+\text{Cu})$ and $\text{Ag}/(\text{Zn}+\text{Pb}+\text{Cu})$ gave most information. In combination with other methods, this approach might also assist in the exploration for specific sediment hosted massive sulphide deposits. We have extracted 450 chemical analyses from 67 well documented sulphide mineralisations distributed in the Mofjellet and the Plurdalen Groups. These meta-sedimentary units are presently considered as particularly promising for the discovery of sediment hosted massive sulphide deposits in the Norwegian part of the Scandinavian Caledonides.

The data employed in the present study were largely retrieved from the ore geological database at the Geological Survey of Norway that, from Nordland County alone, contain more than 800 analysis from over 200 metallic occurrences.

6 GEOLOGICAL SETTING

Massive to semi-massive sulphide ores that vary in size from a few tons to more than 6 million tons, are confined to two and three narrow stratigraphic levels in the Plurdalen and the Mofjellet Groups, respectively (Fig. 1). Whole rock Rb/Sr geochronology on a meta-granite (Marker, 1983) and a concordant U/Pb zircon age obtained from a gabbro (Senior and Andriessen, 1990) constrain the upper ages of the Plurdalen and Mofjellet Groups to 572 ± 32 and 576 ± 7 Ma. An approximate maximum age for the time of sedimentation corresponding to 590 to 600 Ma, has been reached by comparing the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for massive marbles from the Plurdalen Group with the ratio estimated for marine carbonates in the past 900 Million years (Bjerksgård et al., *in prep*).

The Mofjellet Group is primarily composed of meta-sedimentary gray quartzo-feldspathic gneiss intercalated with kyanite-mica gneiss and ortho-amphibolite. Massive sulphides are particularly abundant in three narrow stratigraphic corridors, each of which cover less than 300 meters of the stratigraphy. The ore-bearing lithology is characterized by kyanite-mica gneiss, either with white mica or with biotite as the dominant phyllosilicate.

The Plurdalen Group is dominated by dark colored calcareous mica- and garnet-mica schist intercalated with calcitic and dolomitic marbles, graphitic schist, calc silicate schist and ortho-amphibolite. Most of the massive sulphide occurrences are confined to the contact between a thin, persistent calc-silicate horizon and a calcite marble.

An angular imbricated structure with the Mofjellet Group thrusted up on the Plurdalen Group divides the two groups from each other (Marker, 1983). Although separated by an imbricated thrust, it is inferred from regional geological interpretations that the two groups originally formed close to each other in a marginal continental setting (Marker, 1983).

The entire area was exposed to upper amphibolite facies metamorphism and four episodes of folding (F_1 - F_4) during the Caledonian orogenesis (Marker, 1983). F_1 - F_3 comprises mega-scale isoclinal to open transversal structures trending E-W, whereas the F_4 episode was co-axial with

the NNE-SSW orientation found elsewhere in the Scandinavian Caledonides. Thrusting between the Mofjellet and Plurdalen Groups occurred prior to or during F₁.

7 DISTRIBUTION OF ORE-FORMING ELEMENTS

Sulphide mineralized samples were analyzed for 26 elements with the ICP-AES technique. ICP analysis were conducted on 500 mg samples after digestion with 3 ml of Aqua Regia for one hour at 95 °C, whereas Au, Pt and Pd were fused with fire assay fluxes before ICP-AES analysis. Major element concentrations in unmineralized samples were obtained from fused glass discs with XRF analysis which was also applied to pressed powder tablets for minor element concentrations.

ACME analytical laboratories (Canada) conducted ICP-AES analysis and the Geological Survey of Norway conducted the XRF analysis.

Four occurrences from the Plurdalen Group and the Mofjellet Group, that are representative for their respective units, will be described in more details. The following descriptions are based on publications by Kruse (1979), Olerud (1979), Marker (1983) and own studies.

Most of the occurrences in the Plurdalen Group are strata-bound and spatially associated with a laterally persistent calc-silicate horizon that can be followed for 15 kilometers along strike. This horizon vary in thickness from a few to about 50 meters although, occasionally, it wedges out and disappear. The mineral assemblage includes fine- to medium-grained clinopyroxene, garnet, epidote, amphibole, quartz and sub-ordinate amounts of calcite, which give the rock a dark green massive appearance. The sulphides are situated in the calc-silicate horizon and in the adjacent calcite-dolomite marble and can be divided in three types. One variety is characterized by stratiform semi-massive to massive layers composed of coarse-grained pyrrhotite and pyrite with sphalerite and chalcopyrite and minor amounts of galena. The other type is characterized by conformable thin laminae and lenses, up to a few centimeters thick, and composed of coarse-grained pyrrhotite, pyrite, sphalerite and chalcopyrite. Finally, some sulphide occurrences form veins and breccia fillings of quartz and calcite together with pyrrhotite, chalcopyrite and sphalerite.

In the Mofjellet Group, the vast majority of sulphide ores are stratiform and confined to kyanite-mica gneisses occurring at three stratigraphic levels. The gneisses are medium-grained and composed of variable proportions of white mica, biotite and hornblende together with quartz, garnet and feldspars, and they are classified as muscovite-, biotite-muscovite, biotite- and finally, biotite-hornblende gneisses. Weak disseminations of pyrite and pyrrhotite provides the gneisses with a characteristic rusty weathering crust that can be followed along strike for 20 kilometers from west to east in the Mofjellet Group. In contrast to the Plurdalen Group, the Mofjellet Group contains hundreds of tiny sulphide ore occurrences interspersed with a few sub-economic to economic deposits. In most of the occurrences it is possible to find both disseminations and massive bands and layers up to several meters thick. The occurrences are dominated by pyrite and/or pyrrhotite with minor sphalerite, galena and chalcopyrite, accessory sulphosalts and supergene marcasite.

The four examples of sulphide occurrences listed in Table 1 represents the range of chemical compositions found in the Mofjellet and the Plurdalen Groups. Like all the other occurrences included in this study, they are relatively small and uneconomic, although, temporary mining operations are known from Sæterdalen and Hesjelia. Larger deposits has been avoided in this study because macro scale zonation of the ore-forming elements, as it is known from the

Mofjellet deposit, complicates a bulk estimate of the chemical composition. Hesjelia and Hammeren, both of which belong to the Mofjellet Group, demonstrate the range of compositions known from this group. Not surprisingly, Zn, Cu and Pb are the dominant ore-forming elements, but with a zinc ratio of 74, Hammeren is much more enriched in Pb than Hesjelia which has a ratio of 99. Hammeren is also more enriched in Au and Ag (Table 2) when compared to Hesjelia whereas the Cu/Zn and the S/Fe ratios are comparable. In the Plurdalen Group, represented by Håkshaugen and Sæterdalen, the occurrences contain more Cu than sulphide mineralisations in the Mofjellet Group. Sæterdalen, representing one end member, could go for a Cu-ore with >2 % Cu and only a few hundreds ppm of Zn and Pb. However, the zinc ratio is 76, and, therefore, compares well with Hammeren in the Mofjellet Group. Håkshaugen represents the opposite end member in the Plurdalen Group in having higher concentration of Zn compared to Cu. Characteristic for the Plurdalen Group, and in contrast to sulphides in the Mofjellet group, both Håkshaugen and Sæterdalen have S/Fe ratios that are lower than unity.

When all 67 sulphide occurrences are included, it becomes clear that the Plurdalen Group indeed contain higher proportions of Cu relative to Zn, Pb and Ag when compared to the Mofjellet Group (Fig. 2a-c). On the average, the Cu/Zn, Cu/Pb and the Cu/Ag ratios are 16, 4 and 3 times higher in the Plurdalen Group (Table 2). Gold and silver is significantly enriched in the Mofjellet Group having Au/(Zn+Pb+Cu) and Ag/(Zn+Pb+Cu) ratios that are three times higher when compared to the Plurdalen Group (Table 2). From Fig. 3a-c it is evident that the highest relative concentration of Au and Ag in particular are found in the eastern parts of the Mofjellet Group.

Although the Mofjellet and Plurdalen Groups clearly can be distinguished from each other when it comes to Cu, Ag and Au, Fig. 3a documents that Zn and Pb does not show any preference for one group or the other. In both groups the zinc ratio ($100\text{Zn}/(\text{Zn}+\text{Pb})$) is close to 86 (Table 2). In this context it should be noted that the average zinc ratio reported from the largest deposits in the region vary between 60 and 80. However, these ratios are estimates based on data from the mining companies and may, therefore, reflect the economically viable parts of the deposits, rather than the bulk average employed in this study.

8 DISCUSSION

Given the contrasting geological setting of sulphide occurrences in the Mofjellet and Plurdalen Groups, it is not surprising that they can be distinguished from each other based on the distribution of Cu, Au and Ag although the zinc ratio is similar. A zinc ratio of 86 is relatively high gathering that the occurrences are regarded as sediment-hosted sulphide. When plotted in the common Cu-Zn-Pb ternary (Fig. 4), mineralisations from both the Mofjellet and the Plurdalen Groups cluster in the field where volcanic hosted sulphide deposits normally will plot. However, the geological setting in lithologies by far dominated by meta-sedimentary rocks deposited on a continental margin (Marker, 1983), seems to preclude a strictly volcanic exhalative origin. Some input of volcanioclastic material is likely given the high density of ortho-amphibolites in the Mofjellet Group. The proportions between Pb, Zn and Cu in the unmineralized rocks from the Mofjellet Group are similar to that found in the sulphide occurrences (Fig. 3d). This relationship imply that the sedimentary protholiths hosting the ore could also be the source of the metals. Comparable ore-metal ratios between the massive sulphides and the source rocks has also been documented for occurrences elsewhere in the world (see summary in Franklin et al., 1981). In contrary to this genetic concept, Huston and Large (1987) suggests that the zinc ratio is a function of the temperature and the activity of

chlorine in a saturated ore-bearing solution. According to Huston and Large, the zinc ratio in the source rock should have a minimal influence on the ratio in the sulphide mineralisations. If it is assumed that the ore-bearing solutions were saturated with Zn and Pb and that the salinity varied between 0.5 and 1.5 M NaCl a zinc ratio of 86 would imply temperatures of <150 °C (Huston and Large, 1987). A precise estimate of the ore-forming temperatures in the Mofjellet and Plurdalen Groups is complicated by deformation and metamorphism although the many ortho-amphibolite units suggest crustal stretching and a relatively high geothermal gradient. An increase in the salinity of the ore forming solutions would have a stronger effect on the solubility of Zn than of Pb and, therefore, lead to a higher zinc (Huston and Large, 1987).

Chlorine is by far the most important complexing agent for Zn and Pb (Ruaya and Seward, 1986; Huston and Large, 1987). In contrast to these metals, Cu can be dissolved both as chlorine and as bisulphide complexes (Crerar and Barnes, 1976). From Barnes (1979), it is known that the stability field of the most important complexing bisulfides ion, HS⁻, increases at alkaline conditions in a reducing environment. With extensive units of calcareous lithologies and graphitic schist buffering the pH and the oxygen fugacity toward alkaline and reducing conditions, respectively, the Plurdalen Group fulfill these requirements. Under these conditions, cuprous copper (Cu^{2+}) is strongly soluble as bisulphide complexes (Crerar and Barnes, 1976) whereas Zn would be only mildly soluble (Barnes, 1967) and Pb practically would be insoluble. Given these conditions in the Plurdalen Group, much higher proportions of Cu compared to the Mofjellet Group (Fig. 2a-c), would be expected.

The significantly higher concentration of Au and Ag in the Mofjellet Group can not be ascribed to the complexing capacity of one ligand or the other because Au and Ag, under the appropriate conditions, are strongly soluble as both chloride or bisulphide complexes (e.g. Brimhall and Crear, 1989). More probably, the higher proportions of precious metals in the Mofjellet Group should be ascribed to a higher concentration of these metals in the source rocks. Chemical analysis for these elements in rocks from the Mofjellet Group are not available, but the ortho-amphibolites, being much more frequent than in the Plurdalen Group, could be a possible source of precious metals.

9 CONCLUSIONS AND APPLICATION TO EXPLORATION

Ore element ratio analysis of sub-economic sulphide ores in the Plurdalen and Mofjellet Groups document that occurrences in the Plurdalen Group have higher concentrations of Cu but lower concentration of Au and Ag when compared to the Mofjellet Group. In the Mofjellet Group there is good agreement between the Zn-Pb-Cu distribution in the meta-sedimentary protholith and the distribution of the same metals in the sulphide ores. In the Plurdalen Group, the occurrences have higher Cu/(Zn+Pb) ratios than their inferred sedimentary source rock. This is also evident when they are compared to the occurrences in the Mofjellet Group. Bisulphide complexing of cuprous Cu would selectively enrich the ore-forming solutions in this metal and can, therefore, explain the observed distribution of Cu, Pb and Zn between the Mofjellet and Plurdalen Groups.

The Mofjellet and the Plurdalen Groups have different advantages in a given exploration program aimed at massive sulphide deposits. Particularly the eastern part of the Mofjellet Group has a potential for the discovery of massive sulphide deposits where Au and Ag could be important products together with Zn and Pb. In the Plurdalen Group, a massive sulphide deposit could potentially contain recoverable concentrations of Cu together with Zn and Pb.

10 ACKNOWLEDGMENT

Most of the samples included in this study were gathered by Rune Wilberg who, in collaboration with Leif Furuhaug, also tabulated and organized analysis and sample descriptions in the ore geological database at the Geological Survey of Norway. Parts of this study was supported by Hemnes commune, Nordland county and the mining company, Bleikvassli Gruber A/S. Tor Grenne improved the text and contributed with many constructive comments.
