Summary: Seven gravity cores collected by FFI in the summer of 2003 have been profiled with the X-ray inspection system (XRI) and logged for P-wave velocity, bulk density and magnetic susceptibility using multi-sensor core logger (MSCL). Sediment cores were opened after these non-destructive analyses, sedimentologically described and undrained shear strength was measured on selected intervals. The cores were also subsampled for determining water content, wet density, dry density and grain-size characteristics.

1 INTRODUCTION AND MATERIALS

This report presents results of analytical tests undertaken on 7 sediment cores collected by FFI. The objective of these analyses is to provide sedimentologic and sediment physical properties characteristics, which can potentially be related and/or correlated with sediment acoustic parameters.

2 METHODS AND RESULTS

The laboratory procedures with the sediment cores involved (i) stratigraphic profiling with an X-ray inspection system, (ii) stratigraphic profiling for P-wave velocity, sediment bulk density and magnetic susceptibility using a multi sensor core logger (MSCL), (iii) lithostratigraphic description, (iv) grain-size analysis, (v) determination of geotechnical and physical properties of sediments. Descriptions of methods/procedures are given below. Figures 1-7 in Appendix 1 show compilations of all obtained results and illustrate down-core variations of studied parameters. All tests were carried out at NGU except MSCL logging that was undertaken at the University of Bergen.

2.1 X-ray inspection system (XRI)

The images of the XRI system reflect variable X-ray absorption (transparency) of different sediment components. The XRI system consists of an X-ray tube and an image intensifier that converts invisible X-rays into visible light. A CCD camera is used to capture the visible image. The size of an XRI image depends upon specific settings, typically covering 10-15 cm long sediment intervals. The sediment core is placed between the X-ray tube and the image intensifier; different core sections can be inspected by sliding the assembled X-ray tube and image intensifier along the core. X-ray transparency of a sediment is strongly influenced by the grain-size and the images are generally lighter for the fine-grained sediments and darker for coarse-grained sediments. XRI is a handy, non-destructive method to study the texture and structure of sediments, to characterize the distribution of gas pockets, shells, wood fragments and clasts, and to interpret the disturbances caused by bioturbation, gas escape or shear. The possibility to rotate the core simultaneously with imaging facilitates detailed geometric analyses of specific structural features.

In Appendix 1, the XRI documentation is given as sequences of digital images where each individual image corresponds to ca. 13 cm sediment intervals. The scale at the side of the images shows the depth in centimetres from the sediment surface or from the core section top in case of multiple sections. Individual images from all cores have been montaged to provide the complete XRI sequence. The enclosed CD contains 2 video clip files (SC3-2-sec1 and SC3-2 sec2) that were obtained from both sections (upper - sec1 and lower - sec2) of core SC3-2 while steadily moving the assembled X-ray tube and image intensifier along the core.

2.2 Multi sensor core logger (MSCL)

The GEOTEK manufactured Multi Sensor Core Logger (MSCL) at the University of Bergen was used to study physical properties of sediments by means of gamma-ray density, P-wave velocity and magnetic susceptibility. The MSCL consists of a conveyor system, a central unit assembly including three sensors, a microprocessor and a computer. The conveyor system has two track sections, mounted and aligned on either side of the central unit, and a belt driven pusher block which is driven in either direction by a stepper motor and gear box assembly. The central unit assembly incorporates a compressional wave (P-Wave) logger, a gamma ray attenuation logger and a magnetic susceptibility loop. Automation is achieved through the use of an internal processor, interfaced with the rack-mounted computer that controls the entire running process and stores data.

Up to 140 cm long core sections are placed on the right hand track with the top located at the reference position. A conveyor system automatically pushes each core section through the sensor array (incrementally past gamma ray attenuation logger, the p-wave logger and through the magnetic susceptibility coil) with measurements being taken at spatial increments as defined by the user; 0.5 cm and 1 cm step-sizes were used in this study. The computer controlling the conveyor also controls the sensors, so that all data are automatically correlated. Adjacent core sections are loaded on to the conveyor by the user when prompted by the software commands. In this way a complete core can be logged in a continuous process while the raw and processed data are displayed graphically in real time on the monitor. Complete control of the graphic display is provided, both in terms of the presentation and processing protocols. Both raw and processed data are saved in formats suitable for exporting to other software environments for further data manipulation or data presentation. Spreadsheets with processed MSCL data for all seven cores are given as Excel files on the enclosed CD.

2.2.1 Gamma ray density

Density is determined by measuring the attenuation of gamma rays through the cores. The gamma ray attenuation unit comprises a 10 millicurie Cesium-137 capsule (housed in a 150 mm diameter primary lead shield) with both 2.5 and a 5.0 mm collimators and a sodium iodide scintillation detector (housed in a 150 mm diameter collimated lead shielding to minimize any background radiation). A density resolution of better than 1% depending upon counting time used and core condition is normally achieved. The source and detector are mounted diametrically across the diameter of the core.

A narrow (pencil size) beam of gamma rays with energies principally at 0.662 MeV is emitted from the Cesium -137 source and passes through the diameter of the sediment core. At these energy levels Compton scattering is the primary mechanism for the attenuation of the gamma rays in most sedimentary material. The incident photons are scattered by collision with electrons encountered in the core and there is a partial energy loss. This attenuated gamma beam is measured by the Sodium Iodide detector. The Compton scattering of the photons is directly related to the number of electrons in the path of the gamma ray beam. The bulk density of the sediment is calculated by comparing the attenuation of gamma rays through the

sediment core to the attenuation of the gamma rays through a standard of aluminium density calibration billet, mounted into the liner of exactly the same type as the sediment core. However, the plastic liner used to obtain the studied sediment cores had unusually small diameter to fit any of calibrations billets supplied by the MSCL manufacturer. In order to be able to run the calibration this particular liner, a special aluminium billet was designed.

However, comparisons of MSCL bulk density results with below described wet density measurements have revealed systematic inconsistencies between different methods; these methodological problems are discussed in section 2.5.2.

2.2.2 Magnetic susceptibility

The magnetic susceptibility Bartington loop (150 mm) sensor (MS2B) is used in the MSCL system. A low intensity non-saturating alternating magnetic field is produced by an oscillator circuit in the sensor loop. Changes in the oscillator frequency caused by the sediment in the sensor loop are measured and converted into volume specific magnetic susceptibility values (SI units). The magnitude of the magnetic susceptibility values is dependent on the type of sediment, content of magnetic minerals and the volume of sediment within the coil. Identical cores of varying diameters will give different magnetic susceptibility values but will show the same down core profile. The calibration of the magnetic susceptibility loop, performed using a standard of known magnetic susceptibility, gives 5% calibration accuracy.

Density and magnetic susceptibility profiles shown in Appendix 1 display a general correspondence of these two parameters. However, density signal is obtained from thinner (< 1 cm) sediment interval compared to magnetic susceptibility (4-6 cm thick interval) hence the density logs have proven to be more specific and useful defining stratigraphic boundaries.

2.2.3 P-Wave velocity

The P-Wave logger system consists of two rolling compressional wave transducers (PWT), with soft couplings and a centre frequency around 220 kHz. These PWT's are spring-located on either side of the core to generate and detect short ultrasonic pulses. A short 220 kHz compressional wave pulse is produced at the transmitting transducer at a repetition rate of 1 kHz. This wave pulse travels through the core and is detected by the receiving transducer and the time of flight of the wave pulse is measured. Timing measurements have an accuracy of 50 ns providing velocity accuracy of about 0.2%, depending on core thickness and condition. Calibration can be achieved using a length of core line filled with distilled water of known temperature and velocity. The p-wave travel time is corrected for the P-wave travel time delay caused by the core liner and the electronics of the system.

P-wave velocity logs given in Appendix 1 show that most of the velocity values cluster around ca. 1600 m/s, consistent with the expected values for clayey-silty sediments. However, some parts of cores, most frequently the upper portions, show occasionally scattered profiles with values spread over the wide range. These abrupt jumps on P-wave velocity profiles are evidently not controlled by changes in the sediment character, but most probably reflect bad contact and/or open, air-filled spaces in the sediment liner (air-filled spaces were often observed in between liner wall and core sample) that blunder the measurement.

2.3 Lithostratigraphic description

Lithostratigraphic description was undertaken on split cores that were obtained by cutting through the liner plastic lengthwise and pulling a steel wire through the sediment. The stratigraphic logging focused upon sedimentary structures and texture.

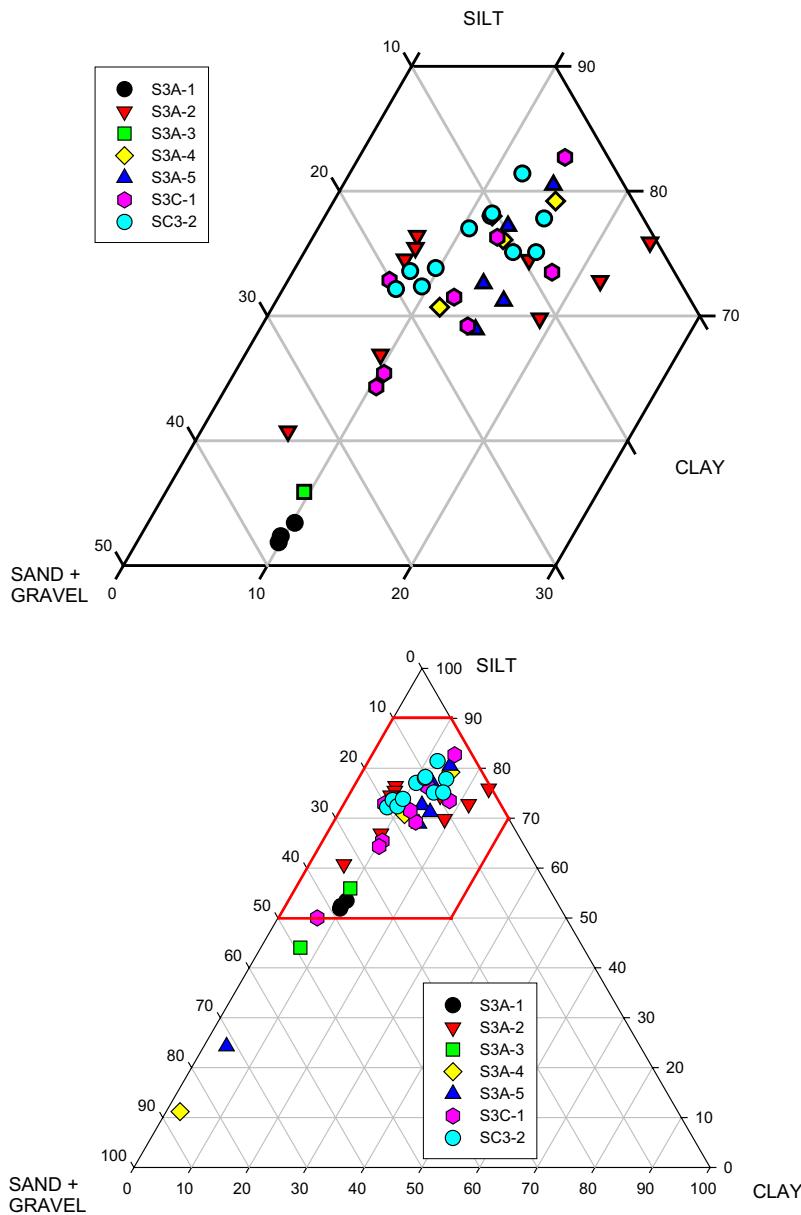

Fig. 1. Ternary plot of all grain size analyses. Upper diagram is a close-up of the plot area with the majority of data points (bordered by red lines).

2.4 Grain-size analyses

For grain size analyses ca. 2 cm thick sediment slices were typically obtained from the following sediment depths depending upon the core length; 10, 25, 50, 75, 100, 125, 150, 175, 200 and 225 cm. Occasionally, up to 5 cm deviations from this sampling scheme were allowed if the desired sampling interval overlapped with the stratigraphic boundary.

Altogether 45 samples were analysed using sieving for fractions coarser than 2 mm and laser diffraction technique using Coulter LS 200 for fractions finer than 2 mm. Samples were oxidised with H₂O₂ to remove organic matter prior to analyses. The sample suspensions used in Coulter LS 200 were dispersed in ultrasonic bath.

Figure 1 shows the distribution of all grain size results on the ternary plot of clay (<2 µm), silt (2-63 µm) and sand-gravel (>63 µm). Stratigraphic variations of median grain size are given in Appendix 1. Complete sets of obtained grain size characteristics are found in Appendix 2.

2.5 Determination of geotechnical and physical properties of sediments

The sampling scheme (10 cm, 25 cm, 50 cm etc.) deployed for grain size analyses was also used to study the geotechnical and physical properties of sediments and the down-core trends of these parameters.

2.5.1 Undrained shear strength

The Falling Cone apparatus was used to measure sediment shear strength. The split core was placed underneath the cone holder with the tip of the cone touching the sample. The penetration depth of the cone into the sediment after releasing the cone is proportional to the undrained shear strength. Note that the values of undrained shear stress may bear a systematic error due to compaction and dewatering during transport and storage prior to analyses.

2.5.2 Water content, wet density and dry density

These parameters were determined with the aid of a thin-wall steel cylinder with known volume and weight. This cylinder was inserted into the sediment and known volumes of wet, undisturbed sediments were subsampled. Weights of wet and dry (drying at 105 °C for 24 hours) subsamples, combined with the known volume, allowed calculating water content, wet density and dry density according to the following formulas:

$$\text{Water content} = \text{Weight of pore water} / \text{Weight of dry sediment}$$

$$\text{Wet density} = \text{Weight of wet sample} / \text{Volume of wet sample}$$

$$\text{Dry density} = \text{Weight of dry sample} / \text{Volume of wet sample}$$

Wet density values obtained by determining the weight of known volume should ideally coincide with the MSCL bulk density values. Figure 2 shows the correspondence between wet and bulk densities, and illustrates that MSCL bulk density values are systematically higher

than wet density values. All data points except one sandy-gravely sample from S3A-4 display a systematic ca. 0.3 g/cm^3 offset (Fig. 2).

During calibration a uniform density and related attenuation capacity of the gamma rays were assumed for aluminium billets supplied by the MSCL manufacturer and the aluminium billet that was made for the purpose of this particular study. This may not have been the case, and it is possible that the newly made calibration billet has higher gamma ray attenuation capacity in comparison to the original MSCL billets. This difference in gamma ray attenuation capacity may have thus caused slightly wrong calibration and resulted in systematically elevated (by ca. 0.3 g/cm^3) MSCL bulk density values.

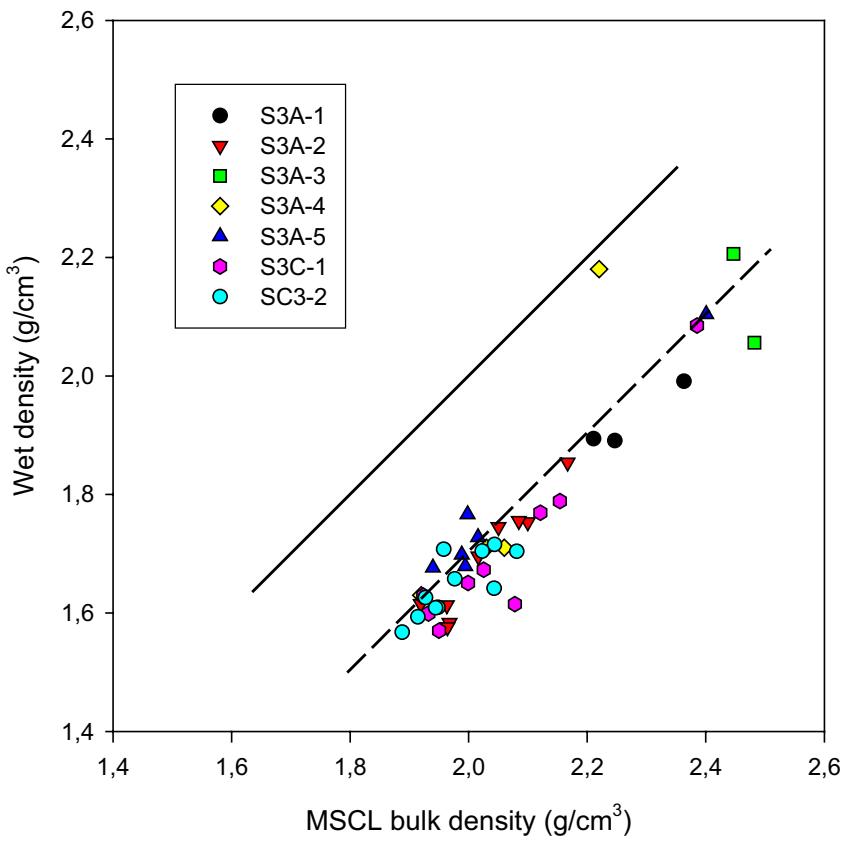

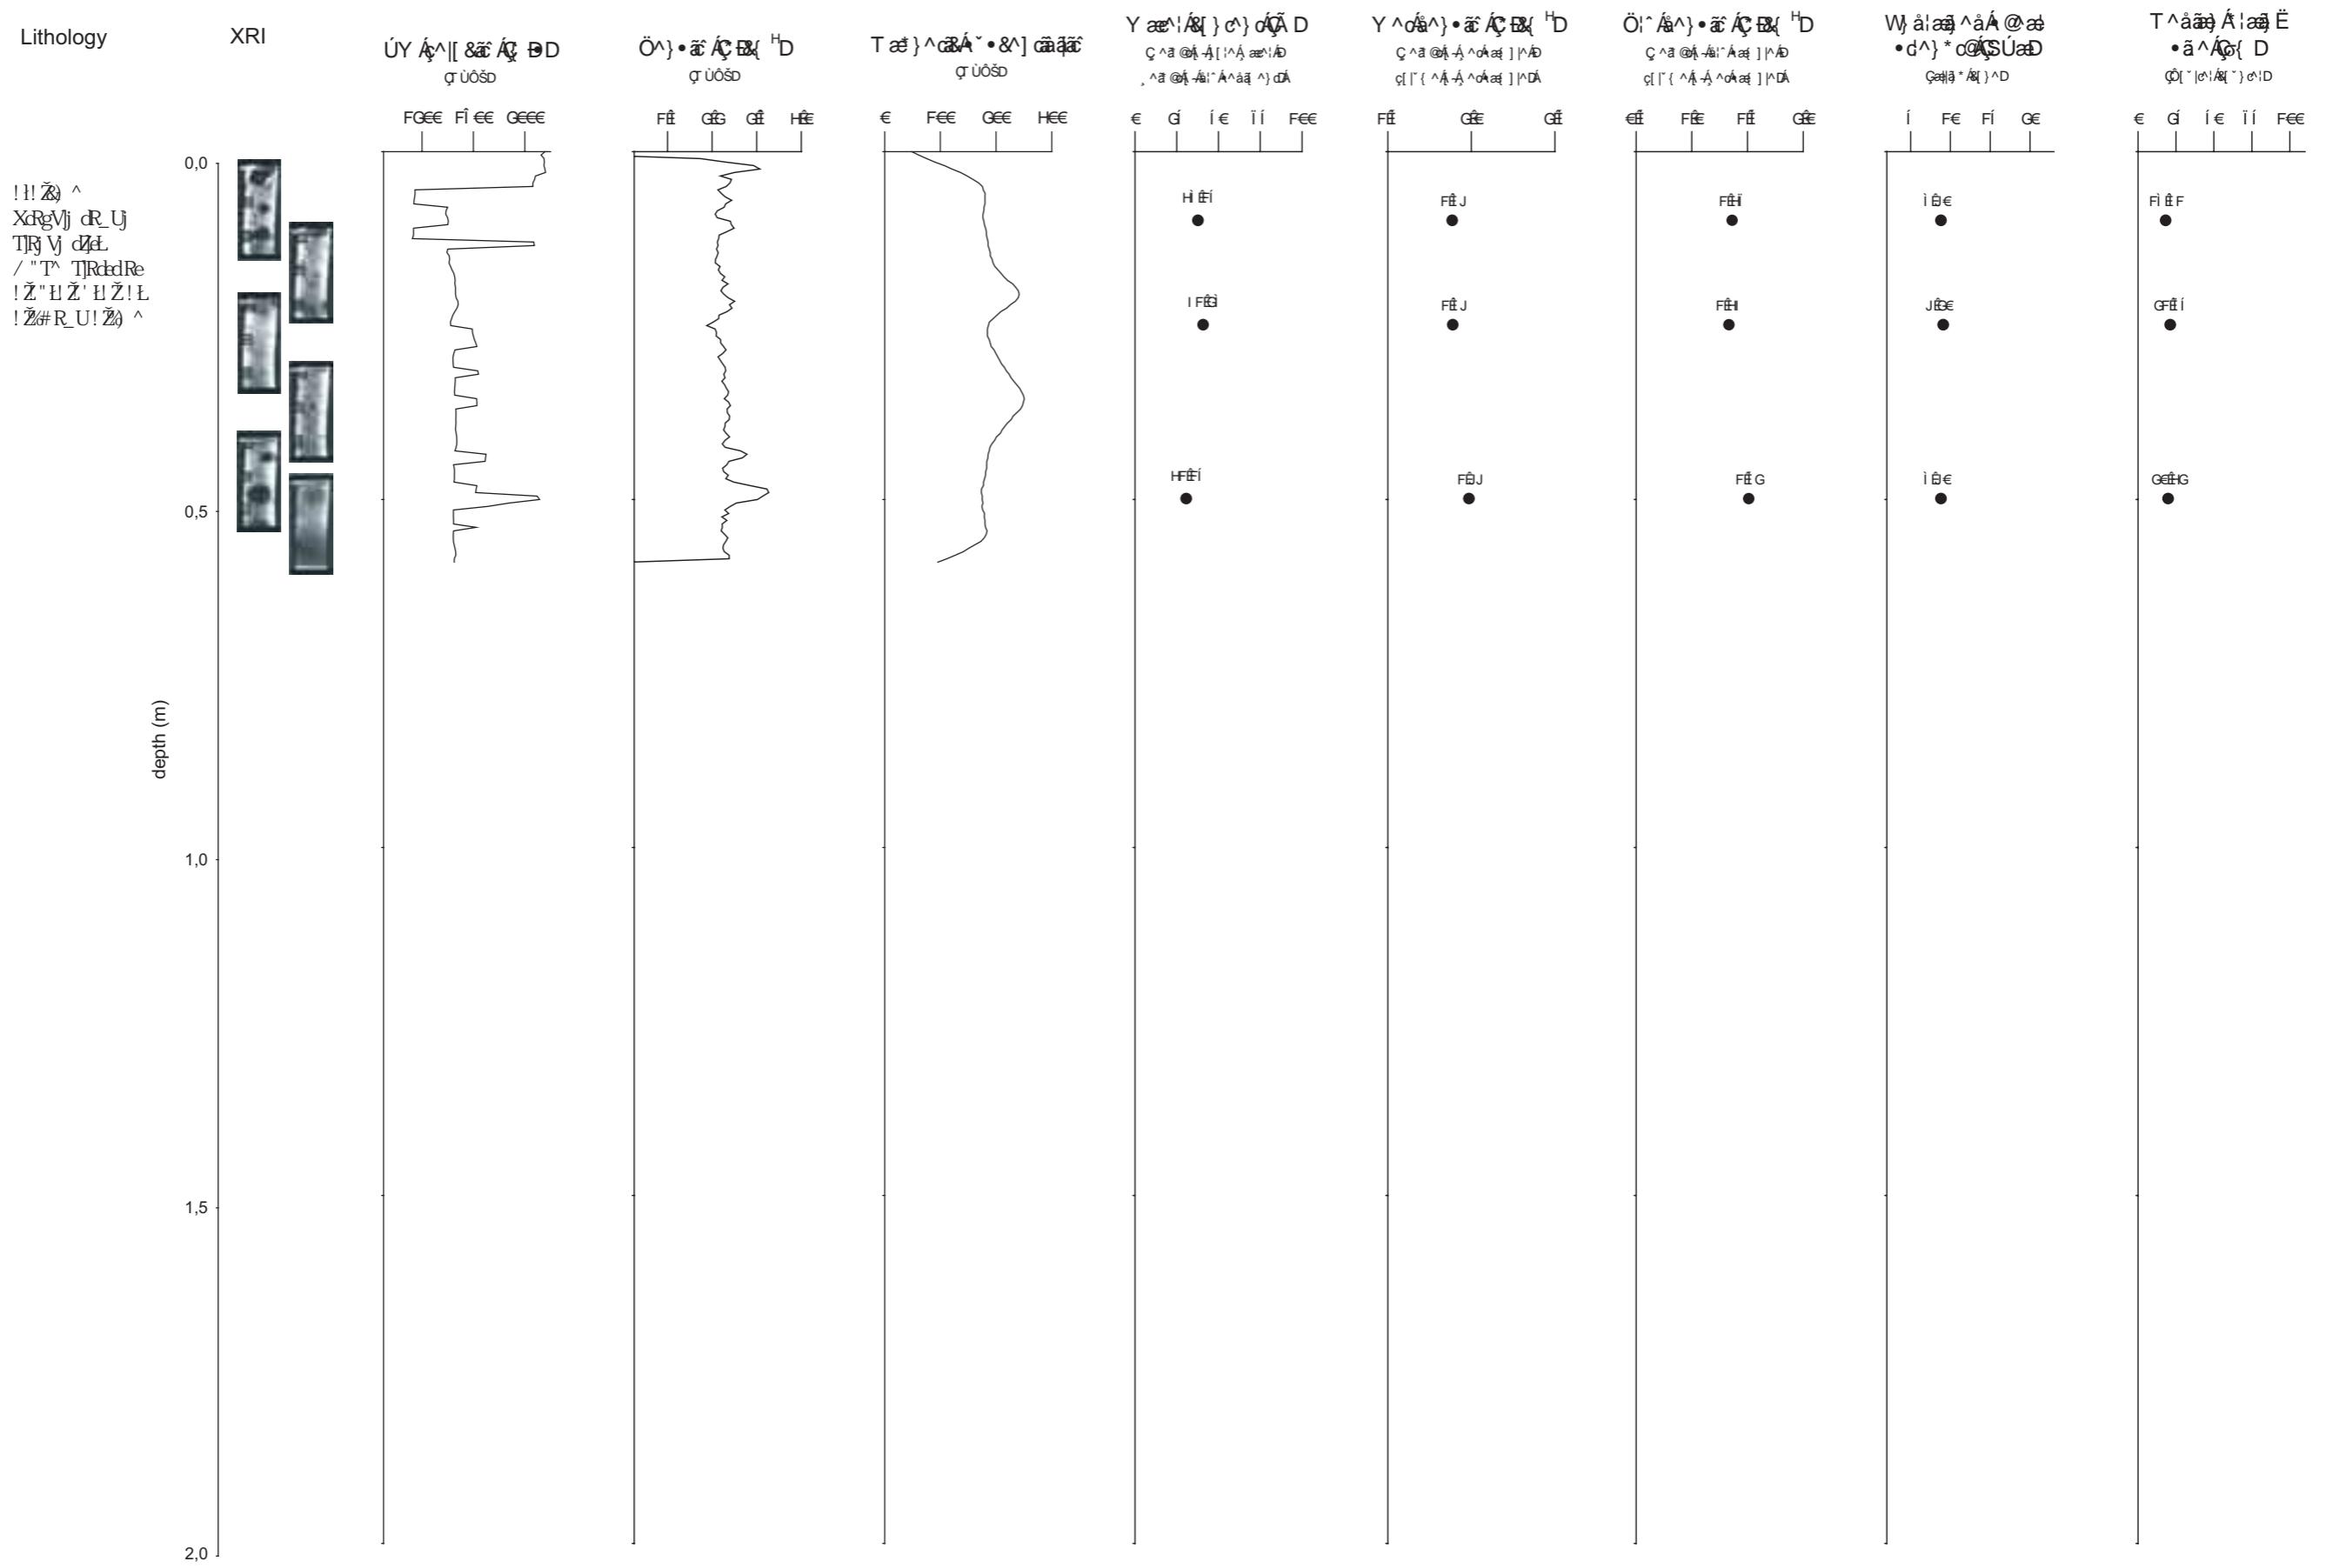

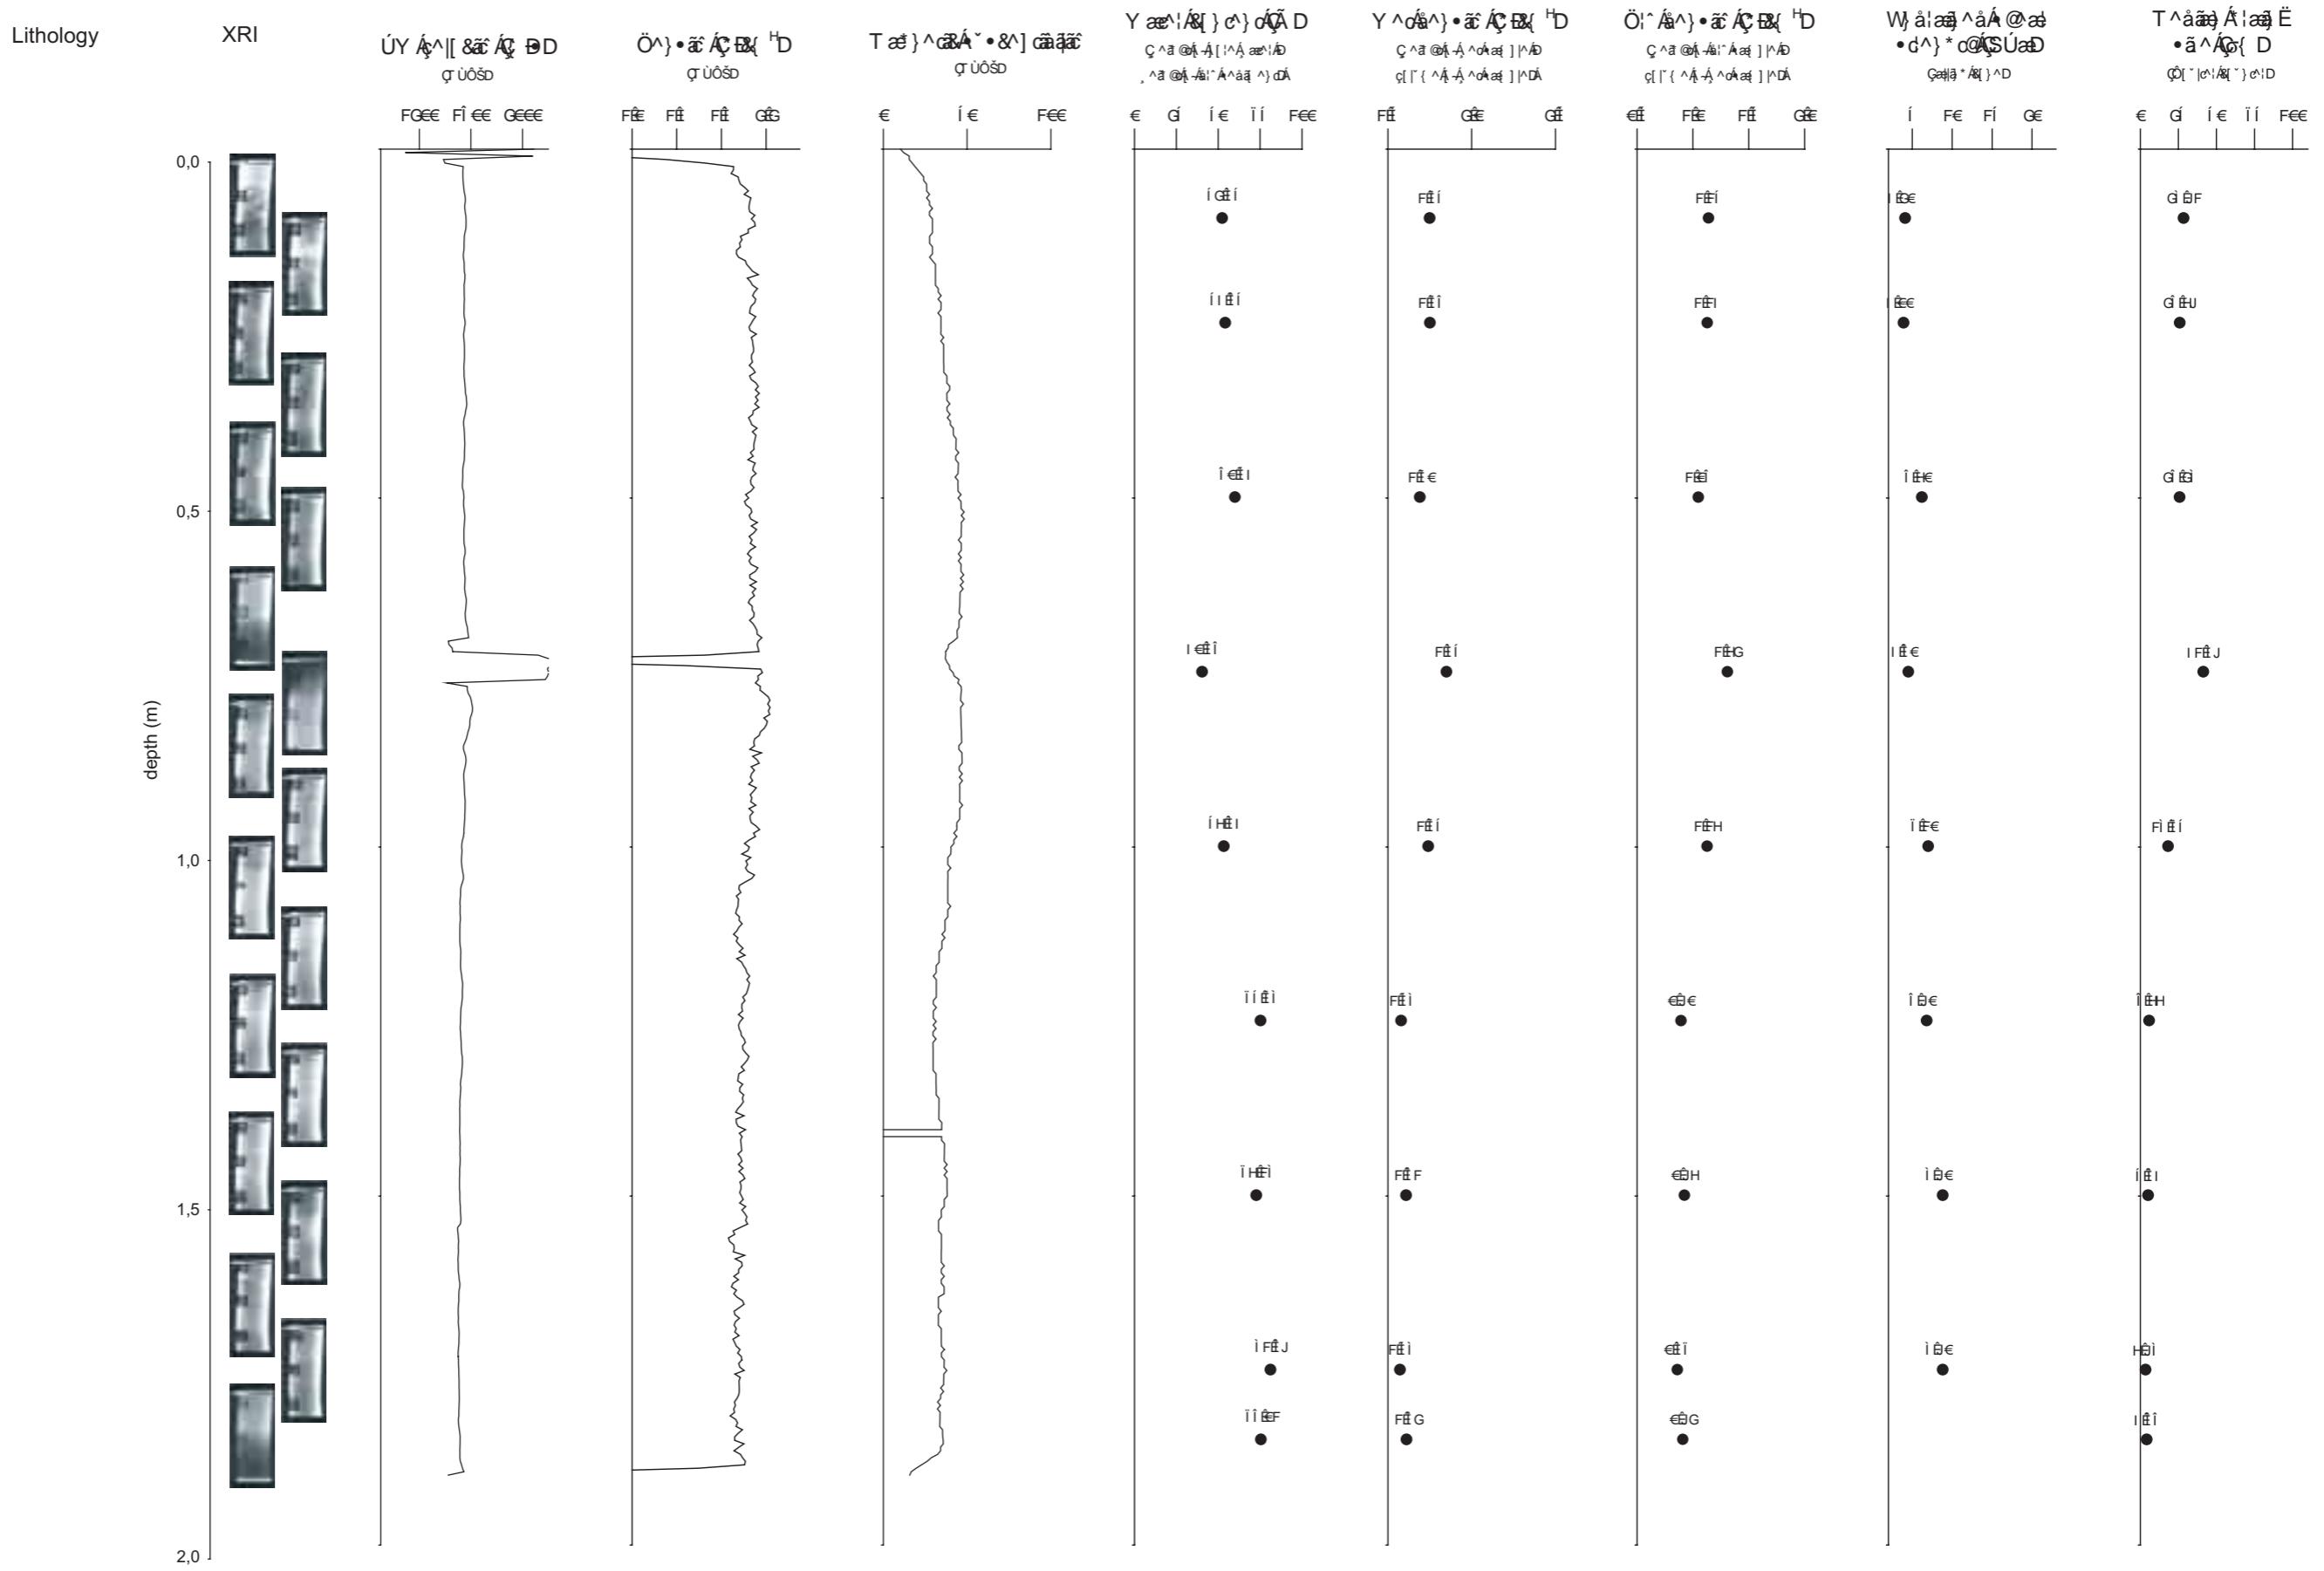

Fig. 2. Correlation diagram for MSCL bulk density and wet density, obtained by determining the weight of known sample volume. Solid line shows the expected correlation; dashed line indicates the offset of $0.3 \text{ g}/\text{cm}^3$.
