Summary:					
<p>The results presented here are based on samples collected by the author during ODP Leg 170, 16. October- 17. December, 1996, and subsequent analyses at the laboratories of the Geological Survey of Norway in Trondheim, Norway. The main objectives for thoroughly documenting the chemistry of the pore fluids and solids are:</p> <ol style="list-style-type: none"> <li>1) to identify the distribution of key elements and isotope ratios between pore fluids and various solid phases,</li> <li>2) to quantify the fluxes of these key elements and isotopes into the subduction zone, and</li> <li>3) to utilize these data for evaluating geochemical and material mass balances, as well as constraining the importance of underplating (Kimura et al. 1997, p. 74). Ultimately it is the concentration data of the key elements in the sediments and the pore fluids which are necessary for answering the question of how much material is subducted. Fluorine in pore fluids and in solids is one of the key elements in this setting.</li> </ol> <p>In the reference section, borehole 1039, sediments in the upper 130 m contains on average 4500 mg/kg F. The lower biogenic ooze from about 200-380 mbsf contains on average 900 mg/kg F. The gabbro at the base of the borehole contains about 4000 mg/kg F. An attempt to identify which minerals contain the F has been only partially successful. Grains containing 2400 to 6200 mg/kg f have been spotted on the SEM by wave-length dispersive XRF. It is evident that F is associated with detrital minerals diagnostic of the ash debris. These could be amphiboles, volcanic glass or tephra. However, F does also seem to be a component of the biogenic fraction in the lower section since it is only partially diluted by the carbonates. In borehole 1040 the upper 500 m contains about 3000 mg/kg F. A slight increase is observed below the decollement at 330-360 mbsf. Below 500 mbsf the average F-concentration drops to 700 mg/kg.</p> <p>In the reference section, borehole 1039, pore fluids contain less than 1.0 mg/L F down to 160 mbsf. Between 160 mbsf and 320 mbsf there is an almost symmetric peak with maximum 2.0 mg/L F at 220 mbsf. A similar peak is identified at a stratigraphically equivalent position in borehole 1040 where the peak has a maximum of 2.7 mg/L F.</p> <p>The consistently high concentration of F in the diatomaceous ooze is not matched by a similar higher concentration in the pore fluids. The maximum concentration of F in these are found in the biogenic zone, and the peak is more accentuated in borehole 1040 below the decollement than in the reference section in 1039 west of the trench. This could suggest a source of these waters in the subsurface to the east. The average flux of fluorine subduction in borehole 1040, sections U1, U2, and U3 is estimated to be 181, 193 and 136 g/yr/cm arc length, respectively.</p>

## 1 INTRODUCTION

The results presented here are based on samples collected by the author during ODP Leg 170, 16. October- 17. December, 1996, and subsequent analyses at the laboratories of the Geological Survey of Norway in Trondheim, Norway. The stratigraphy of each borehole is described in detail in Kimura et al. 1997, and the exact position of the samples are given by their depth in meters below the seafloor (mbsf).

The main objectives for thoroughly documenting the chemistry of the pore fluids and solids in a subduction zone are:

- to identify the distribution of key elements and isotope ratios between pore fluids and various solid phases,
- to quantify the fluxes of these key elements and isotopes into the subduction zone, and
- to utilize these data for evaluating geochemical and material mass balances, as well as constraining the importance of underplating (Kimura et al. 1997, p. 74).

The concentrations of the key elements in the sediments and pore fluids are needed to answer the question of how much material is subducted. Fluorine in the pore fluids and solids is one of those key elements in this setting.

Sediments and pore waters collected on Leg 170 and later analysed for fluorine, represent a reference section through the sedimentary section west of the subduction zone in borehole 1039 (430 m deep) and a section through the accretionary prism and the underlying subducted sediments east of the trench in borehole 1040 (660m deep)(Fig. 1).

## 2 METHODS

The concentration of F has been measured using an ion-selective electrode (Adriano & Doner, 1982) in 36 sediment and porewater samples from borehole 1039 and 65 sediment and porewater samples from borehole 1040 (Fig. 2, 3, 4 and 5). Details of this procedure are as follows:

*1)Determination of fluoride in marine sediment samples using ion-selective electrode after digestion by alkali fusion.*

a) Alkali fusion (after McQuaker & Gurney 1977, in Page et. al. 1982)

The samples were first freeze-dried and milled to a fine powder in an agate mill about 0.25 g sample was accurately weighed and transferred into a nickel crucible. The sample was wetted with a small amount of de-ionised water, 3.0 ml 17N NaOH added and the crucible placed in a drying oven at 150°C for approximately 1 hour, until the NaOH had solidified. The crucible was then transferred to a muffle furnace at 300°C and the temperature was gradually raised to 600°C. The sample-alkali mixture was allowed to fuse for 30 minutes at this temperature. The crucible was then removed from the muffle furnace and allowed to cool to room temperature. The NaOH cake was dissolved by adding 5 ml de-ionised water and gentle warming. 4.0 ml concentrated HCl was then added, under stirring, to adjust the pH to 8 - 9, the pH being checked using pH paper. The acidified sample was then cooled, transferred to a 100 ml volumetric flask, diluted to 100 ml with water and filtered through "Schleicher & Schüll" black band filter paper. Acidification and filtration of the sample removes Al and Fe which

may be present and which would interfere with the subsequent determination of the fluoride using an ion selective electrode.

#### b) Determination of fluoride in the digested sample

A sample of 10 ml was added to 10 ml TISAB (Total Ionic Strength Adjusted Buffer) solution. The potential was read after stirring 10 minutes - as for water samples - and compared to a calibration curve prepared using the «single solution technique» (McQuaker & Gurney, 1977).

#### 2) Determination of fluoride in porewater samples using ion-selective electrode

Determination of fluoride in the porewater samples was carried out using a modified version of the Norwegian standard method NS 4740 (NSF, 1975).

The water samples were thawed and diluted 1:10 with Milli-Q<sup>®</sup> water. A 10 ml diluted sample was added to 10 ml TISAB buffer solution, pH 5.4, prepared according to NS 4740\*, and the potential read after stirring for 10 minutes on a magnetic stirrer. Fluoride concentration was determined by comparison of the potential reading with a standard curve, prepared using standard NaF solutions. Ten milliliters of the standard solution was added to 10 ml EDTA buffer solution, pH 5.4 and the potential was read after stirring for 10 minutes.

\* TISAB buffer solution: 57 ml glacial acetic acid + 58 g NaCl in 500 ml H<sub>2</sub>O, + 4.0g EDTA (C<sub>6</sub>H<sub>10</sub>(N(CH<sub>2</sub>COOH)<sub>2</sub>)), pH adjusted to 5.4 with 5M NaOH, finally diluted to 1000 ml with water

#### **NOTE:**

*NGU-Lab is not accredited for these methods.*

*According to NS 4740, the lower detection limit for determination of fluoride in water by the ion-selective electrode method used here, is 0.1 ppm. The method also quotes results from a ringtest where analyses of a synthetic water sample by 111 laboratories gave a relative error of 0.7%, with a relative standard deviation of 3.6%. NGU-Lab is currently carrying out tests to check the precision and accuracy of the method as performed in our labs.*

*With respect to the analysis of fluoride in sediment samples, earlier trials at NGU-lab using a very similar, but not identical, method, and standard soil samples, gave a lowest recovery of 47% (for a Canadian calcareous C-horizon soil with 6% Al<sub>2</sub>O<sub>3</sub>) and a highest recovery of 88% (for a Canadian podzolic soil. With 15% Al<sub>2</sub>O<sub>3</sub>).*

### **3 FLUORINE IN SEDIMENTS**

In the reference section, borehole 1039, the upper 130 m of diatomaceous ooze with ash and silty clay with ash, contains on average 4500 mg/kg F (Table 1). The lower biogenic ooze from about 200-380 mbsf contains on average 900 mg/kg F. The fluorine content is inversely correlated with the calcium carbonate content (Fig. 2 and Kimura et al. 1997). The gabbro at the base of the borehole contains about 4000 mg/kg F.

An attempt to identify which minerals contain the F has been only partially successful. Grains containing 2400 to 6200 mg/kg F have been spotted on the SEM by wave-length dispersive XRF (Fig. 6, 7, 8 and 9). It is evident that F is associated with detrital minerals diagnostic of the ash debris. These could be amphiboles, volcanic glass or tephra. However, F does also seem to be a component of the biogenic fraction in the lower section since it is only partially diluted by the carbonates. Authigenic carbonate fluorapatite, the primary mineral phase of sedimentary phosphorite, is common on the Peru continental margin (Froelich et al. 1983),

but has not been identified in the sediments offshore Costa Rica. However, F could be a minor element in fish remains.

In borehole 1040, the upper 500 m contains about 3000 mg/kg F (Tab.1 and Fig.3). A slight increase is observed below the decollement at 330-360 mbsf. Below 500 mbsf the average F-concentration drops to 700 mg/kg. The F-content is inversely related to the content of calcium carbonate.

#### **4 FLUORINE IN POREWATERS**

The concentration of F in sea water is 1.3 mg/L (Krauskopf, 1979). In the reference section, borehole 1039, pore fluids contain less than 1.0 mg/L down to 160 mbsf. Between 160 mbsf and 320 mbsf there is an almost symmetric peak with maximum 2.0 mg/L F at 220 mbsf. This peak is independent of the F content of the sediments. Calcium in the pore fluids increases in an overlapping interval with a peak at 280 mbsf (Kimura et al. 1997). Alteration of the brown mafic glass-rich crystal-vitric mafic ashes in the calcareous section is most likely responsible for the very high Ca-values in this portion of the sedimentary section (Kimura et al. 1997, p. 74). This could explain the relatively high concentration of F in the pore fluids as well. A similar peak is identified at a stratigraphically equivalent position in borehole 1040 where the peak has a maximum of 2.7 mg/L F. This could suggest a source of these waters in the subsurface to the east.

#### **5 ESTIMATION OF FLUORINE SUBDUCTION FLUX**

The average flux of fluorine subduction in borehole 1040, section U1, is estimated to be 181.3 g/yr/cm arc length (Tab. 2). Similar estimates for section U2 and U3 are 193 and 136 g/yr/cm arc length. Minimum and maximum estimates are 88 and 302 g/yr/cm arc length.

#### **6 DISCUSSION AND CONCLUSIONS**

The consistently high concentration of F in the diatomaceous ooze is not matched by a similar higher concentration in the pore fluids. The maximum concentration of F in these are found in the biogenic zone, and the peak is more accentuated in borehole 1040 below the decollement than in the reference section in 1039 west of the trench. This could suggest a source of these waters in the subsurface to the east. Further details on fluid flow in this area are discussed in Silver et al. 2000a.

\*) Procedure for estimating subduction flux in 1039 and 1040.

The calculation of the general dry weight mass flux ( $F_s$ ) is done by the equations (1) or (2), depending on whether the water content ( $w_w$ ) or the porosity ( $n$ ) is known;

$$F_s = v * h * \rho_t * [1 - (w_w/100)] \quad (1)$$

$$F_s = v * h * [1 - (n/100)] * \rho_s \quad (2)$$

$v$  = Convergence rate (cm yr<sup>-1</sup>)

$h$  = Sediment thickness (cm)

$\rho_t$  = Bulk density (g cm<sup>-3</sup>)

$w_w$  = Water content (wt%)

$n$  = Porosity (vol%)

$\rho_s$  = Specific density of the solid material (g cm<sup>-3</sup>)

The specific density ( $\rho_s$ ) of the solid part of the sediment is calculated from bulk density and porosity:

$$\rho_s = [\rho_t - (n/100)] / (1 - n/100) \quad (3)$$

The final result of equations (2) and (3) is:

$$F_s = v * h * [\rho_t - (n/100)] \quad (4)$$

As an example the data for the section 1040 (U1) are given;  $v = 8.2$  cm yr<sup>-1</sup>,  $h = 4970$  cm,  $\rho_t = 2.0$  g cm<sup>-3</sup> and  $n = 66$  vol% and the equations (4) is calculated:

$$F_s = 8.2 \text{ cm yr}^{-1} * 4970 \text{ cm} * [2.0 - (66/100)] \text{ g cm}^{-3} = \underline{54610 \text{ g yr}^{-1} \text{ per cm arc length}} \quad (1)$$

The calculation of the flux of the chemical component  $x$  ( $F_x$ ) is then given by the equation;

$$F_x = F_s * C_x \quad (4)$$

$C_x$  = Concentration of the chemical component  $x$  ( ppm =mg kg<sup>-1</sup> dry weight)

Using the average fluorine-composition of section 1040 (U1)  $C_F = 3.32$  g/kg the fluorine-flux ( $F_F$ ) is calculated:

$$F_F = 54610 * 3.32 = \underline{181.3 \text{ g yr}^{-1} \text{ per cm arc length}}$$
